19 Running Head: Environmental induced plasticity in frog morphology

20 * Corresponding autor: tejedo@ebd.csic.es

21 ABSTRACT: In organisms with complex life cycles, environmentally induced plasticity
22 across sequential stages can have important consequences on morphology and life history
23 traits such as developmental and growth rates. However, previous research in amphibians
24 and other ectothermic vertebrates suggests that some morphological traits are generally
25 insensitive to environmental inductions. We conducted a literature survey to examine the
26 allometric responses in relative hind leg length and head shape of postmetamorphic anuran
27 amphibians to induced environmental (temperature, resource level, predation and
28 desiccation risk) variation operating during the larval phase in 44 studies using 19 species.
29 To estimate and compare plastic responses across studies we employed both an index of
30 plasticity and effect sizes from a meta-analysis. We found contrasting trait responses to
31 different environmental cues. Higher temperatures increase development more than growth
32 rate and induce smaller heads but not overall shifts in hind leg length. By contrast, an
33 increment in resource availability increases growth more than development, with a parallel
34 increase in hind leg length but no change in head shape. Increase in predation risk decreases
35 both development and growth rates and slightly reduces relative hind leg length, but there is
36 no change in head shape. Pond desiccation induces quick development and low growth
37 rates, with no changes in morphology. Across environments, both hind leg and head shape
38 plasticity were positively correlated with growth rate plasticity. However, plasticity of
39 developmental rate was only correlated with head shape plasticity. Overall, these results
40 suggest that environmental trends predicted by global warming projections, as increasing
41 pond temperature and accelerating pond desiccation, will significantly influence hind leg
42 and head morphology in metamorphic frogs, which may affect performance and, ultimately,
43 fitness.

44 KEY WORDS: morphology, plasticity, temperature, resources, pond desiccation, predation

45 risk, meta-analysis, global warming.

46

47 **1. INTRODUCTION**

48 Environmentally-induced variation in body shape occurs in many taxa and
49 phenotypic plasticity in morphology has been found in response to several environmental
50 factors such as diet (Wimberger 1992, Thompson 1999), temperature (de Jong et al. 2010,
51 Trotta et al. 2010), and resource allocation (Nijhout & Emlen 1998, Stern & Emlen 1999,
52 Canale & Henry 2010). However, previous research on amphibians and other ectothermic
53 vertebrates has suggested that size-independent metric shapes are generally insensitive to
54 environmental induction (Arnold & Peterson 1989, Blouin & Loeb, 1991, Forsman 1996,
55 Blouin & Brown 2000).

56 Development is a branching process in which undifferentiated precursor tissues may
57 determine different phenotypes occurring later. Therefore, environmental influence on
58 phenotypes may be especially relevant when this happens at early stages of the ontogeny
59 (e.g. Lindström 1999). This may be of particular interest in animals with complex life
60 cycles, as in most invertebrates and amphibians, where environmental induction during the
61 embryo, larval or pupal stage can have strong effects on morphology after metamorphosis
62 (Emerson 1986, Giménez 2006).

63 In amphibians, four major ecological factors, commonly encountered during the
64 larval stage, can drastically affect metamorphic traits: temperature, trophic resources (via
65 food availability or larval competition), habitat permanence (via desiccation of temporary
66 ponds, the common breeding environment for most amphibian species) and predator
67 pressure (via behavioural trade-offs between growth and activity), (Alford 1999, Bruce
68 2005). Global warming will result in a general rise in pond temperatures, but it will also
69 affect the rainfall regimes and environmental predictability across the globe, thus resulting

70 in shorter pond durations during dry years (McMenamin et al. 2008). Increased severe
71 droughts may also affect biotic interactions presumably with a combined increase in both
72 resource competition and predation. Therefore, climatic change is likely to affect all the
73 main ecological factors affecting amphibian plasticity at metamorphosis.

74 Much of the research on amphibian developmental plasticity has concentrated on
75 environmental induction on size and time to metamorphosis (Wells 2007). Only recently
76 studies have reported on the allometric (size independent) shifts in hind leg length and head
77 shape to varying growth conditions during the larval stages (Tejedo et al. 2000a, Relyea
78 2001, Van Buskirk & Saxer 2001, Gómez-Mestre & Buchholtz 2006, Niecieza et al. 2006,
79 Richter-Boix et al. 2006a, Orizaola & Laurila 2009), which are partly due to allometric
80 differences in the relative growth rates of the body and either hind leg or head (Emerson
81 1986, Emerson et al. 1988). In frogs, hind leg length and head shape are well suited traits
82 for analysing environmental effects on morphological variation since both traits have clear
83 and testable morphofunctional implications. Relatively longer hind legs increase jumping
84 performance (Zug 1978, Emerson 1978, Tejedo et al. 2000a,b, Gomes et al. 2009), and
85 rapid adaptive coevolution between hind leg length and rate of movement has been
86 suggested in the invasive toad *Rhinella marina* (Phillips et al., 2006). In addition, wider
87 skulls and longer jaws may facilitate the intake of larger prey (Emerson 1985 Emerson &
88 Bramble, 1993).

89 To predict the environmental outcome of climatic change, especially on low
90 dispersal organisms such as amphibians, it is necessary to assess the magnitude and
91 direction of plasticity in fitness related traits in response to different environmental factors,
92 and the potential of populations to evolve (Parmesan 2006, Chown et al. 2010). Current

93 results in amphibians have revealed contrasting patterns in morphological inductions
94 between different environmental factors. For instance, although increase in temperature and
95 resource availability is predicted to boost both developmental and growth rates, their effects
96 on hind leg length appear to be the opposite: longer legs when tadpoles are raised at
97 increased resources (Emerson 1986, Tejedo et al. 2000a) and shorter when growing at
98 higher temperatures (Gómez-Mestre & Buchholtz 2006). Therefore, it is currently difficult
99 to establish a general pattern of how larval environment affects the morphological plasticity
100 at metamorphosis.

101 In this study we used meta-analytic techniques to describe the magnitude and
102 direction of plasticity in hind leg length and head shape of postmetamorphic juvenile frogs
103 induced by four main ecological factors operating during the larval phase: temperature,
104 desiccation risk, resource availability and predation risk. All these factors will presumably
105 be affected by global climate warming.

106 2. METHODS

107 2.1. Data

108 We examined a total of 44 experiments to test whether variation in these four
109 environmental factors determine the allometric response in morphological shape after
110 metamorphosis in frogs. We considered information for 19 different taxa (including the
111 Klepton *Pelophylax* kl. *esculenta*; see Annex I) reported in 11 published studies (24
112 experiments) between 1991-2009 and 10 unpublished studies carried out between 1995-
113 2007 (20 experiments). All these studies, covering 20 mesocosms and 24 laboratory
114 experiments, manipulated environmental conditions the larvae experienced. Resource
115 availability (17 experiments), temperature (11 experiments), non-lethal predation risk (11

116 experiments), and pond desiccation risk (5 experiments), are known agents imposing
117 substantial effects on larval growth and development in amphibians (Alford, 1999). Forty-
118 one and forty of the considered studies provided quantitative data on relative size of hind
119 leg length / tibiofibula length, and head width, respectively, together with information on
120 time to and size at metamorphosis as well as larval growth rates (see Annex I).

121 We estimated adjusted mean differences in morphology between environments by
122 using an ANCOVA (GLM module of the Statistica software; Statsoft, Inc., 2007). Body
123 mass ($\ln \text{mass}^{1/3}$) was used as a covariate for most of the studies. However in *Scaphiopus*
124 *holbrooki*, *Spea multiplicata*, *Spea intermontana*, *Pelobates cultripes* (Gomez-Mestre &
125 Buchholtz 2006, Gomez-Mestre & Buchholtz, unpublished; *Hyla cinerea* (Blouin & Loeb
126 1991); and *Rana cascadae* (Blouin & Brown 2000), snout-vent length (SVL) was employed
127 as covariate, and the first principal component (PC1) was used as a covariate in
128 *Discoglossus galganoi* (Nicieza et al. 2006). The environment x body size interaction term
129 was included in the model to test for heterogeneity of slopes. Initial analyses showed that,
130 in most occasions, this interaction was not significant ($P > 0.25$). Thus, the treatment term
131 tests whether frogs raised in contrasting environments differed in size-independent shape.
132 In mesocosm experiments, individual responses were analysed and a mixed model was
133 fitted, treating environment as a fixed factor and tank as a random variable nested within
134 environments.

135 We were also interested in analysing the dependence of post-metamorphic shape on
136 larval developmental and growth rates across species and experiments. Thus, we considered
137 developmental time as the time elapsed from the start of larval feeding phase (Gosner stage
138 25, Gosner 1960) to metamorphic climax with foreleg protrusion (Gosner stage 42). Size at

139 metamorphosis was estimated as mass at metamorphosis after full tail resorption (Gosner
140 stage 46), or mass at Gosner stage 42 (Capellán & Nicieza 2007), or SVL (Blouin & Loeb
141 1991, Gómez-Mestre & Buchholz 2006, Gómez-Mestre & Buchholtz unpublished data).
142 Growth rate was estimated as body size at metamorphosis divided by developmental time.

143 **2.2. Analyses**

144 To estimate and compare plastic responses across studies, we employed both an
145 index of plasticity providing the change in percent, and effect sizes derived from a meta-
146 analysis (Rosenberg et al. 2000). To estimate the index of plasticity we first removed the
147 differences in mean size-adjusted hind leg length and head width, and mean time and size
148 to metamorphosis and growth rates, at low temperature or resource level, or at no
149 desiccation or predation risk treatments (Low treatments) by setting these variables to 100
150 % (i.e. Hind leg length_{Low} = 100). Subsequently, we expressed the same variables at the
151 high temperature or resource level, and at predation or desiccation risk treatments (High
152 treatments) as a fraction of this total, and plasticity was estimated as the difference between
153 mean traits under High and Low environmental conditions (Plasticity Hind leg length =
154 $((\text{Hind leg length}_{\text{High}} / \text{Hind leg length}_{\text{Low}}) - 1) * 100$). Since this value of plasticity
155 represents a dimensionless estimate of relative change it can be used to compare different
156 traits and experiments. Positive values of plasticity indicate that the trait increases at the
157 High environments (high temperature or resource level, presence of desiccation or
158 predation risk), whereas a negative value indicates that the increase occurred at the Low
159 environments (low temperatures or resource level, no risk of desiccation or predation).
160 Significant values of plasticity were considered if 95 % confidence limits do not overlap
161 with zero.

162 In addition, we estimated the magnitude of plasticity in morphological and life
163 history traits by parallel analyses conducted with effect sizes from a meta-analysis
164 (Metawin 2.1, Rosenberg et al. 2000). *Hyla versicolor* and *H. cinerea* were excluded from
165 some of the analyses because lack of information on sample sizes and standard errors
166 prevented us from estimating effect sizes. The magnitude of the overall effect size is
167 generally interpreted as “small” if Hedges’ $d = 0.2$, “medium” if $d = 0.5$, “large” if $d = 0.8$,
168 and “very large” for values of $d > 1.0$ (Cohen 1969). Effect sizes were considered
169 significant if 95 % confidence intervals did not cross zero

170 The associations between plasticity estimates in hind leg length and head shape with
171 developmental time, mass and growth rates plasticities were analyzed by using Pearson’s
172 correlation and multiple regression analyses to tease apart the partial contributions of
173 plasticity in developmental or growth rates to morphological plasticity. All the analyses
174 were performed using the STATISTICA 8.0 Statistical Package (Statsoft, Inc 2007).

175

176

3. RESULTS

177 Ecological factors acting during the larval phase induce strong changes in larval life
178 history traits in anuran amphibians (Table 1, Fig. 1). Increasing resource levels and
179 temperature strongly accelerated both larval development and growth rates. However, we
180 found contrasting trait responses to different environmental cues. Higher temperatures
181 increase development more than growth rates, whereas an increment in resource availability
182 results in greater enhancement of growth than development. An increase in predation risk
183 induced a small decrease in both development and growth rates, and pond desiccation
184 increased developmental rate and reduced growth rate slightly. Mass at metamorphosis

185 responds differentially depending on the ecological factor, with larger size when resources
186 are plenty but smaller size with increases in temperature, predation or pond desiccation
187 risk.

188 Larval environmental conditions affected the morphology of anurans at
189 metamorphosis (Table 1, Fig. 1). For hind leg length, 32 studies out of 43 (74.4 %) reported
190 significant results, whereas only 24 out of 41 studies (58.5%) reported significant allometry
191 in head shape (test of comparison between proportions, $P = 0.126$, see Annex I). Most of
192 the experiments found that allometric plasticity in morphology was low or moderate for
193 both traits (hind leg: plasticity index range: - 5.6 to + 10.3 %, Hedges' d range: - 0.64 to +
194 2.63; head: plasticity index range, - 13.3 to + 17.3 %, Hedges' d range. - 2.12 to + 2.04,
195 Annex I). Resource availability and the presence of non-lethal predators induced the
196 strongest changes in hind leg length by either elongating hind legs with increasing resource
197 levels or shortening them with predation risk (Table 1, Fig. 1). Head shape allometry was
198 only affected by temperature, implying a reduction in head size with increasing
199 temperatures (Table 1, Fig. 1).

200 Hind legs were relatively longer when either growth rate or mass at metamorphosis
201 was environmentally enhanced ($r = 0.52$, $P = 0.0005$, $N = 41$, Fig. 2a, $r = 0.52$, $P = 0.0004$,
202 $N = 43$, respectively). However, there was no significant relationship between plasticity in
203 hind leg length and plasticity in developmental time ($r = - 0.20$, $P = 0.20$, $N = 41$, Fig. 2b).
204 Allometric changes in head width covaried positively with growth rate ($r = 0.35$, $P = 0.027$,
205 $N = 40$, Fig. 3a) and mass at metamorphosis ($r = 0.53$, $P = 0.0003$, $N = 41$), and also with
206 developmental time, although this result was marginally non significant ($r = 0.29$, $P = 0.06$,
207 $N = 40$, Fig. 3b).

208 Time to metamorphosis and growth rate plasticity were negatively correlated ($r = -$
209 0.44, $P = 0.0036$, $N = 42$). Hind leg length plasticity was explained by the partial
210 contribution of growth rate plasticity after controlling for variation in developmental rate
211 plasticity ($Beta = 0.502$, $P = 0.0007$), but the partial contribution of developmental rate was
212 not significant ($Beta = 0.211$, $P = 0.129$). Head width plasticity was explained by partial
213 contributions of both growth rate ($Beta = 0.593$, $P = 0.0002$) and developmental rate ($Beta$
214 $= 0.552$, $P = 0.0005$). Parallel analyses conducted with effect sizes from the meta-analysis
215 (Metawin 2.1, Rosenberg et al. 2000) provided similar trends to those found with our
216 plasticity index and are not shown in detail here.

217

218

4. DISCUSSION

219 In anurans, environmental variation in the aquatic larval habitat promotes shifts in
220 growth and differentiation rates that influence morphological shape at metamorphosis. This
221 is an indication that ecological conditions determine allometric growth between body size,
222 hind legs and head throughout development (Emerson 1986). The environmentally induced
223 plasticity in morphological shape found in anurans via alteration of growth and
224 developmental rates may be widespread also in other organisms (e.g. Strathmann et al.
225 1992, Elphick & Shine 1998, Zijlstra 2003, Moriuchi & Winn 2005).

226 The increase in resource availability induces a consistent response with elongation
227 of hind legs with the exception of *Discoglossus galganoi*, which exhibits a slight non-
228 significant reduction (Niecieza et al. 2006). However, the pattern of increased resource
229 induction on head shape appears inconsistent across the species as some species exhibit
230 wider (e.g. *Rana* species, *Agalychnis callidryas* and *Discoglossus galganoi*, see Annex I)

231 and other narrower heads (*Pelobates cultripes* and *Pelodytes ibericus*, see Annex I). The
232 morphological pattern observed at reduced resource levels (i.e. metamorphs with shorter
233 hind legs and wider heads in some species) seems to mirror less developed morphology as
234 tadpoles approaching metamorphosis tend to elongate the hind legs and narrow the head
235 (Sokol 1984, Hall et al. 1997, Cannatella 1999). A similar trend is found when larvae
236 develop under predation risk (see below). Hence, stressful conditions operating during
237 larval stages (lower resource levels or predation risk) seem to promote a faster whole-body
238 developmental rate that allows larvae to escape from a poor growing environment at the
239 cost of incomplete development of some body parts (e.g. hind legs).

240 Higher temperature during the larval phase induces a significant reduction in
241 metamorph head width. Results across species appear strongly consistent, with the
242 exception of *Rana cascadae* and *Xenopus laevis* which increase head size, however, both
243 plasticity values were non-significant (Blouin & Brown 2000, Gómez-Mestre et al.
244 unpublished). A similar reduction in head width was found in *Xenopus laevis* when
245 temperature was increased only during the metamorphic climax (Walsh et al. 2008), which
246 agrees with the general trend of head reduction at higher developmental temperatures.
247 These results are similar to those found in other ectotherms, showing reduced size of
248 several morphological traits, such as the wings, thorax and head under higher
249 developmental temperatures (French et al. 1998, Ottenheim & Volmer 1999, Stevens 2004,
250 Santos et al. 2006, Trotta et al. 2010). In amphibians, a reduction of head size may have
251 some negative consequences on individual performance, since most species are gape-
252 limited predators and reduced head size may decrease ingestion capability in juveniles and
253 reduce the size and type range of potential prey (Emerson & Bramble 1993, Maglia, 1996).

254 Interestingly, increasing temperature did not induce a response in hind leg length with an
255 effect size not different from zero. Although developmental time was clearly reduced and
256 growth rate was enhanced, an expected hind leg elongation similar to that found with
257 increasing resources, was only found for ranid frogs (*Rana cascadae*, Blouin & Brown
258 2000, and *R. lessonae*, Orizaola & Laurila 2009) whereas a shortening in hind legs was
259 found for the rest of species. This contrasting pattern may reflect a phylogenetic signal
260 although the small sample size (six species) precludes any power in the statistical analysis
261 of phylogenetic autocorrelation (Abouheif et al. 1999). Therefore, more information is
262 required to depict a general trend of temperature effect on hind legs in amphibians and its
263 proximate mechanisms.

264 Exposure to predation risk during larval development promoted changes in
265 allometric shape of metamorphs. High predation risk generally induces shorter relative hind
266 legs. In the present study the data are highly consistent with the exception of the longer
267 hind legs of *Rana sylvatica* frogs emerging from predator treatment (Relyea 2001). This
268 disparity may be explained by the high growth rates exhibited by this species (*R. sylvatica*
269 raised with predators metamorphoses later but at similar size), contrasting with other
270 species which exhibit a strong reduction in growth rates (see Annex I, Fig. 1).

271 Desiccation risk induced a plastic acceleration of developmental rate, with a parallel
272 decline in growth rates and size at metamorphosis. Pond desiccation poses a strong time
273 constraint for development of larval amphibians. The increase in developmental rate and
274 reduction in growth rate is the common response to pond desiccation expressed by larval
275 anurans both at the intraspecific and interspecific level (Brady & Griffiths 2000, Leips et al.
276 2000, Merilä et al. 2004, Richter-Boix et al. 2006b, Richter-Boix, Tejedo and Rezende,

277 unpublished data). The consequences of pond desiccation on allometric shape seem to be a
278 decrease in relative hind legs, although this effect was not significant, probably due to the
279 small sample size (five contrasts for three species). However, we propose that this trend is
280 general as other studies have reported shorter hind legs under pond desiccation risk, for
281 example, in *Scaphiopus couchii* (Newman 1989) and *Rhinella spinulosa* (Márquez-García
282 et al. 2009).

283 Plasticity of hind leg length and head shape was of relatively low or moderate
284 magnitude, especially if compared with plasticity in development, growth rate, or mass at
285 metamorphosis. Therefore, the direct consequences for fitness will require further testing.
286 Interspecific comparisons have suggested that an increase of at least 10% in leg length is
287 needed to have a substantial influence on locomotion (Zug 1972, Emerson 1978). In fact,
288 several recent morphofunctional analyses, where the relative hind leg lengths were
289 experimentally manipulated, have revealed that a small (1-2%) increase of relative hind leg
290 length did not result in a significantly enhanced locomotor performance (Van Buskirk &
291 Saxer 2001, Richter-Boix et al. 2006a; see Annex I). By contrast, a larger increase of
292 relative hind leg length in *R. esculenta* (7.2 %) and *P. punctatus* (8.8 %) under high
293 resource availability (Annex I) determined a concomitant increase of 32.4 % and 34 % in
294 size-adjusted maximum jumping distance, respectively (Tejedo et al. 2000, M. Tejedo, F.
295 Marangoni & C. Pertoldi, unpublished data). Similarly, increases in relative leg length (5.8
296 - 10.3 %) in warm larval environments in *Rana lessonae* populations, increased relative
297 jumping performance by 15.1 - 29.4 % in two out of three studied populations (Orizaola &
298 Laurila 2009). These latter studies suggest that environmentally induced allometries in hind
299 leg length may have important consequences on performance, once a minimum amount of

300 hind leg elongation is attained. Therefore, we can expect that any small advantage may be
301 selectively important considering the intense predation that amphibians suffer especially
302 during metamorphosis and early juvenile life (Arnold & Wassersug, 1978). Recent studies
303 have found that population variation in relative hind leg length correlates with locomotor
304 performance (Ficetola et al. 2006, Phillips et al. 2006). The role that plasticity induced
305 during the larval phase may play in driving this adaptive divergence (e.g. through genetic
306 assimilation) deserves more research (Gómez-Mestre & Buchholtz 2006, Wund et al.
307 2008).

308 In general, plasticity of shape in juvenile frogs across environments is dependent on
309 variation in either developmental and/or growth rate plasticities. Environments promoting
310 higher larval growth rates produce juvenile frogs with relatively longer hind legs and wider
311 heads. Poor growing environments, contrarily, will produce stumpy juveniles with
312 relatively poor jumping performance. However the pattern of integration of developmental
313 rates with postmetamorphic morphology differs between traits. Environmentally induced
314 variation in developmental rates translated in changes in relative head size, but not on
315 relative hind leg length. The variation in elongation of hind leg length at metamorphosis
316 was only affected by variation in growth rates. This conclusion agrees with an experiment
317 designed to tease apart both growth and developmental rate by altering larval growth rates
318 while keeping the pace of developmental rate unchanged. The results (M. Tejedo, F.
319 Marangoni & C. Pertoldi, unpublished data) revealed that the treatment where larval growth
320 was diminished at late pre-metamorphosis (33-34 Gosner stage) resulted in similar
321 developmental rates as in the control but, in contrast to expectations, overall size and
322 relative hind legs were smaller than the control. As a result, and coincident with our

323 analyses, final hind leg shape was more dependent on variations in growth rates than on
324 variation in developmental rate.

325 A final consideration is the persistence of the plasticity: whether the level of
326 plasticity found in hind leg length and head width at metamorphosis can be relatively
327 transient and disappear during the early juvenile growth. In holometabolous insects, the
328 morphological effects of larval and pupae environments on adults are fixed (Boggs 1981).
329 However, environmentally induced changes in amphibians may not be permanent and
330 concomitant to their fitness consequences. In reptiles, duration of thermally induced
331 allometries is short (Shine et al. 1997, Elphick & Shine 1998). This may be the general
332 pattern also in amphibians as found in two pelodytids (*Pelodytes punctatus* and *P. ibericus*;
333 M. Tejedo, F. Marangoni & C. Pertoldi, unpublished data) and one pelobatid frog
334 (*Pelobates cultripes*; M. Tejedo & I. Gomez-Mestre, unpublished). Consequently,
335 compensatory growth processes can result in a more canalised phenotype during the adult
336 stage (Emerson 1986). Thus, in terms of fitness, the biological significance of the
337 developmental plasticity for hind leg shape found at metamorphosis may be time-limited.

338 Global warming will probably increase both air temperature and decrease rainfall
339 amount in many areas of the world (IPCC 2007) which indirectly will determine increasing
340 pond desiccation rates. As our results suggest, increased temperature and pond desiccation
341 risk during anuran larval phase can be predicted to produce smaller-headed and possibly
342 more shorter-legged frogs. However, climate change is also going to affect resource
343 availability, primary production, competition and predation risk in unpredictable ways.
344 These effects are going to be highly system-specific and therefore, the effects of global
345 warming on froglet morphology and fitness are difficult to predict.

346

347 *Acknowledgments.* We wish to acknowledge the ConGen and ThermAdapt programmes
348 (funded by the European Science Foundation) by organizing the workshop “Evolutionary
349 and Physiological Adaptation to Climate Induced Environmental Changes” held in
350 Białowieża, Poland, June 29-July 1, 2009. Thanks to M. Calduch, J. M. de Alba and C.
351 Gómez who helped with the measurements of morphology of metamorphs, and E. Dahl for
352 useful suggestions and linguistic revision. This research was funded by projects PB96-0861
353 and CGL2009-12767-C02-02 to MT. FM was supported by a doctoral grant contract
354 funded by the project CGL2004-01872/BOS to MT. CP was supported by grants from the
355 Danish Natural Sciences Research Council (21-01-0526 and 21-03-0125) and the Marie
356 Curie Fellowship of the European Community Host Development program under contract
357 number HPMD-CT-2000-00009, and REN2001-2647/GLO and MMA-86-2003 to AGN.

Table 1. The numbers present the mean, standard error (SE) and sample size of the plasticity index (%), see main text) and Hedges' d effect sizes (d), bias-corrected 95 % bootstrap confidence intervals (95 % bias CI) and sample size (N) from a meta-analysis, of size-adjusted hind leg length, size-adjusted head width, developmental time, mass at metamorphosis and growth rates in amphibians at the metamorphosis, at different experimental conditions during the larval phase. Positive values of plasticity index and effect sizes indicate that the trait increases at the High environments (high temperature or resource level, presence of desiccation or predation risk), whereas a negative value indicates that the increase occurred at the Low environments (low temperatures or resource level, no risk of desiccation or predation).

Annex I Dataset

Size-adjusted hind leg length and head width, developmental time, mass at metamorphosis and growth rates in amphibians at the

metamorphosis at different experimental conditions during the larval phase: RES: Resource level; TEM: temperature; PRE: predation risk, DES:

Desiccation risk. High and Low indicates values for “high” levels of resources and temperatures and presence of non-lethal predators and pond

desiccation; “low” indicates low levels of resources and temperatures and absence of either predation risk or pond desiccation risk. Data are expressed as mean \pm 1 Standard Deviation. Plasticity in size-adjusted hind leg, size-adjusted head width, time to metamorphosis, mass at metamorphosis and growth rate was expressed both by a plasticity index (% see text) and by Hedges’ d effect sizes (d), expressed as mean d \pm variance from meta-analysis. *Comparison of either relative hind leg length or head width reported as significant in original paper or unpublished study. †: Tibio-fibula length, ^H:Total hind leg length. ‡: Size-adjusted head snout length. §: Snout vent length (mm). ?: Information unknown or not provided.

FIGURE LEGENDS

Figure 1. Mean effect sizes (Hedge's d) and bias-corrected bootstrapped 95% confidence intervals, for morphological (size-adjusted hind leg length and head width) and life history traits (date of metamorphosis, mass at metamorphosis and growth rates), in amphibians at the metamorphosis at different experimental conditions during the larval phase. Effects are statistically significant ($P < 0.05$) if confidence intervals excluded zero. Positive values of d indicate that the trait increases at the High environments (high temperature or resource level, presence of desiccation or predation risk), whereas a negative value indicates that the increase occurred at the Low environments (low temperatures or resource level, no risk of desiccation or predation).

Figure 2. Correlation between size-adjusted hind leg length plasticity and plasticity in either growth rate (a) ($r=0.52$, $P=0.0005$, $N=41$), or developmental time (b) ($r=-0.20$, $P=0.20$, $N=41$) in amphibians at the metamorphosis at different experimental conditions during the larval phase: RES: Resource level; TEM: temperature; PRE: predation risk, DES: Desiccation risk.

Figure 3. Correlation between size-adjusted head width plasticity and plasticity in either growth rate (a), ($r=0.35$, $P=0.027$, $N=40$) or developmental time (b) ($r=0.29$, $P=0.06$, $N=40$), in amphibians at the metamorphosis at different experimental conditions during the larval phase: RES: Resource level; TEM: temperature; PRE: predation risk, DES: Desiccation risk.
